Abstract

Time-resolved electrophysiological measurements such as those offered by magneto- or electro-encephalography (M/EEG) provide a unique window onto neural activity underlying cognitive processes. Typically, researchers are interested in testing whether and when such measures differ across conditions and/or groups. The conventional approach consists in conducting mass-univariate statistics through time followed by some form of multiplicity correction (e.g., FDR, FWER) or cluster-based inference. However, these cluster-based methods have an important downside: they shift the focus of inference from the timepoint to the cluster level, thus preventing any conclusion to be made about the onset or offset of effects (e.g., differences across conditions or groups). Here, we introduce a model-based approach for analysing M/EEG timeseries such as ERPs or timecourses of decoding performance and their differences across conditions or groups. This approach relies on Bayesian generalised additive multilevel models, which output the posterior probability of the effect being above 0 (or above chance) at every timestep, while naturally taking into account the temporal dependencies and between-subject variability present in such data. Using both simulation and actual EEG data, we show that the proposed approach largely outperforms conventional methods in determining both the onset and offset of M/EEG effects (e.g., ERPs difference, decoding performance), producting more precise and more reliable estimates. We provide an R package implementing the approach and illustrate how to integrate it into M/EEG statistical pipelines in MNE-Python.

Short intro/recap about Bayesian (linear and generalised) regression models...

Generalised additive models

See for instance these tutorials (Sóskuthy, 2017; Winter & Wieling, 2016) or application to phonetic data (Wieling, 2018) or this introduction (Baayen & Linke, 2020) or these reference books (Hastie & Tibshirani, 2017; Wood, 2017a)... application to pupillometry (Rij et al., 2019)... GAMLSS for neuroimaging data (Dinga et al., 2021)...

In generalised additive models (GAMs), the functional relationship between predictors and response variable is decomposed into a sum of low-dimensional non-parametric functions. A typical GAM has the following form:

$$y_i \sim \text{EF}(\mu_i, \phi)$$

$$g(\mu_i) = \underbrace{A_i + \mathbf{X}_i \gamma}_{\text{parametric part}} + \underbrace{\sum_{j=1}^{J} f_j(x_{ij})}_{\text{non-parametric part}}$$

where $y_i \sim \text{EF}(\mu_i, \phi)$ denotes that the observations y_i are distributed as some member of the exponential family of distributions (e.g., Gaussian, Gamma, Beta, Poisson) with mean μ_i and scale parameter ϕ ; $g(\cdot)$ is the link function, A is an offset, \mathbf{X}_i is the ith row of a parametric model matrix, γ is a vector of parameters for the parametric terms, f_j is a smooth function of covariate x_j . The smooth functions f_j are represented in the model via penalised splines basis expansions of the covariates, that are a weighted sum of basis functions:

$$f_{j}\left(x_{ij}\right) = \sum_{k=1}^{K} \beta_{jk} b_{jk}\left(x_{ij}\right)$$

where β_{jk} is the weight (coefficient) associated with the kth basis function $b_{jk}()$ evaluated at the covariate value x_{ij} for the jth smooth function f_j . Splines coefficients are penalised

(usually through the squared of the smooth functions' second derivative) in a way that can be interpreted as a prior on the "wiggliness" of the function...

37 Bayesian generalised additive multilevel models

Now describe the Bayesian GAMM... Proper inclusion of varying/random effects in the model specification protects against overly wiggly curves (Baayen & Linke, 2020)...

44 Methods

5 M/EEG data simulation

Following the approach used by Sassenhagen & Draschkow (2019) and Rousselet (2025), we simulated EEG data stemming from two conditions, one with noise only, and the other with noise + signal. As in previous studies, the noise was generated by superimposing 50 sinusoids at different frequencies, following an EEG-like spectrum (see details and code in Yeung et al., 2004). As in Rousselet (2025), the signal was generated from truncated Gaussian with an objective onset at 160 ms, a peak at 250 ms, and an offset at 342 ms. We simulated this signal for 250 timesteps between 0 and 0.5s, akin to a 500 Hz sampling rate. We simulated such data for a group of 20 participants with 50 trials per participant and condition (Figure 1).

We computed the average of the ERP difference (Figure 2)...

55 Model fitting

We then fitted a Bayesian GAM using the brms package (Bürkner, 2017, 2018; Nalborczyk et al., 2019). We used the default priors in brms, that is, weakly informative priors. We ran eight Markov Chain Monte-Carlo (MCMC) to approximate the posterior distribution, including each 5000 iterations and a warmup of 2000 iterations, yielding a total of $8 \times (5000-2000) = 24000$ posterior samples to use for inference. Posterior convergence was assessed examining trace plots as well as the Gelman–Rubin statistic \hat{R} . The brms package uses the same syntax as the R package mgcv v 1.9-1 (Wood, 2017b) for specifying smooth effects.

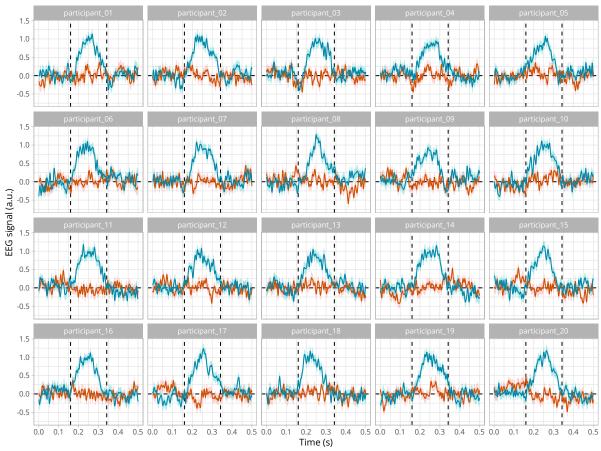

```
# averaging across participants
ppt_df <- raw_df %>%
    group_by(participant, condition, time) %>%
    summarise(eeg = mean(eeg) ) %>%
    ungroup()

# defining a contrast for condition
contrasts(ppt_df$condition) <- c(-0.5, 0.5)

# fitting the GAM
gam <- brm(
    # cubic regression splines with k-1 basis functions
    eeg ~ condition + s(time, bs = "cr", k = 10, by = condition),
    data = ppt_df,
    family = gaussian(),
    warmup = 2000,</pre>
```

Figure 1

```
iter = 5000,
chains = 8,
cores = 8,
file = "models/gam.rds"
)
```

Posterior probability of difference above 0

64

65

66

67

68

69

70

We then plot the posterior predictions together with the posterior estimate of the slope for condition at each timestep (Figure 3).

We then compute the posterior probability of the slope for condition being above $0 + \epsilon$ (Figure 4), with $\epsilon := 0.05$, which can be interpreted as the smallest effect size of interest.

We can also express this as the ratio of posterior probabilities (i.e., p/(1-p)) and visualise the time course of this ratio superimposed with the conventional thresholds on evidence ratios (Figure 5).

Figure 2

Group-level average difference between conditions (mean +/- standard error of the mean). The 'true' onset and offset are indicated by the vertical dashed lines.

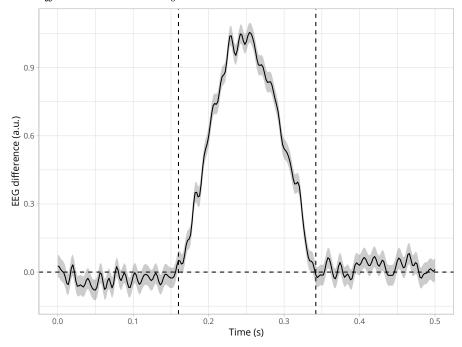

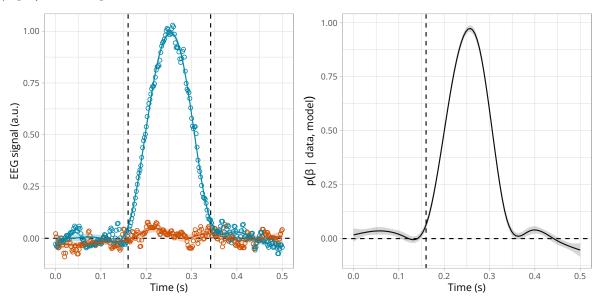

Figure 3

Posterior estimate of the ERP in each condition (left) or directly for the difference of ERPs (right) according to the GAM.

71 Multilevel modelling using ERP summary statistics

Next we fit a hierarchical/multilevel GAM using summary statistics of ERPs (mean and SD) at the participant level (similar to what is done in meta-analysis).

Figure 4

Posterior probability of the ERP difference (slope) being above 0 according to the GAM.

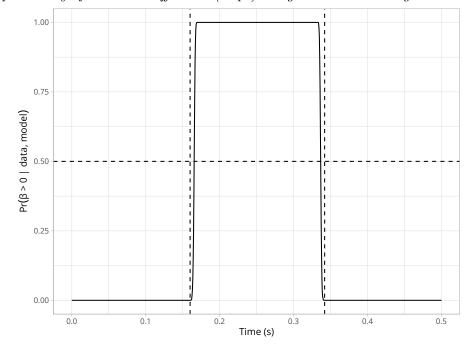

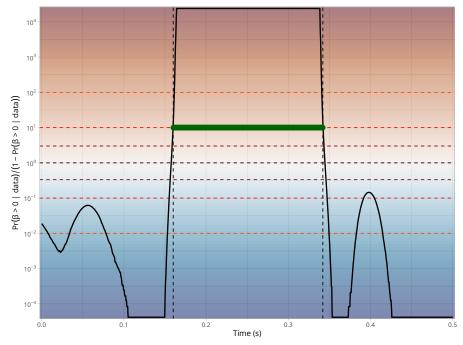

Figure 5

Ratio of posterior probability according to the GAM. Timesteps above threshold (10) are high-lighted in green.

```
# averaging across participants
summary_df <- raw_df %>%
summarise(
    eeg_mean = mean(eeg),
```

```
eeg_sd = sd(eeg),
        .by = c(participant, condition, time)
# defining a contrast for condition
contrasts(summary_df$condition) <- c(-0.5, 0.5)</pre>
# fitting the GAM
meta_gam <- brm(</pre>
    # using by-participant SD of ERPs across trials
    eeg_mean | se(eeg_sd) ~
        condition + s(time, bs = "cr", k = 10, by = condition) +
        (1 | participant),
    data = summary_df,
    family = gaussian(),
    warmup = 2000,
    iter = 5000,
    chains = 8,
    cores = 8,
    file = "models/meta_gam.rds"
```

4 Error properties of the proposed approach

75

76

77

79

We then computed the difference between the true and estimated onset/offset of the ERP difference (error := $|\hat{\theta} - \theta|$), according to various eps and threshold values. Remember that the signal is generated from a truncated Gaussian with an objective onset at 160 ms, a maximum at 250 ms, and an offset at 342 ms. Figure 6 shows that the hierarchical GAM can exactly recover the true onset and offset values, given some reasonable choice of eps and threshold values (e.g., a threshold of 20).

81		eps	threshold	${\tt estimated_onset}$	${\tt estimated_offset}$	error_onset	error_offset
82	1	0.00	13	0.16	0.34	0	0.002
83	2	0.00	14	0.16	0.34	0	0.002
84	3	0.00	15	0.16	0.34	0	0.002
85	4	0.00	16	0.16	0.34	0	0.002
86	5	0.00	17	0.16	0.34	0	0.002

Comparing the identified onsets/offsets to other approaches

We compared the ability of the GAMM to correctly estimate the onset and offset of the ERP difference to widely used methods. First, we conducted mass-univariate t-tests (thus treating each timestep independently) and identified the onset and offset of the ERP difference as the first and last values crossing an arbitrary significance threshold ($\alpha = 0.01$). We then followed the same approach but after applying different forms of multiplicity correction the the p-values. We compared two methods that control the false discovery rate (FDR) (i.e., BH95, Benjamini & Hochberg, 1995; and BY01, Benjamini & Yekutieli, 2001), one method that controls the familywise error rate (FWER) (i.e., Holm-Bonferroni method, Holm, 1979), and two clusterbased methods (permutation with a single threshold and TFCE, Smith & Nichols, 2009). The BH95, BY01, and Holm corrections were applied to the p-values using the p.adjust() function in R. The cluster-based inference was implemented using a cluster-sum statistic of squared tvalues, as implemented in MNE-Python (Gramfort, 2013), called via the R package reticulate v 1.35.0 (Ushey et al., 2024). We also compared these estimates to the onset and offset as estimated using the binary segmentation algorithm, as implemented in the R package changepoint v 2.2.4 (Killick et al., 2022a), and applied directly to the squared t-values (as in Rousselet, 2025). For visualisation and interpretability purposes, we converted p-values to s-values, which can be interpreted as bits of surprising information, assuming a null effect (Greenland, 2019) (Figure 7).

Figure 7

Timecourse of squared t-values and s-values, with true onset (black dashed line) and onsets identified using the raw (uncorrected) p-values or the corrected p-values (BH, BY, Holm).

True onset: 0.16s, Uncorrected onset: 0.174s, BH onset: 0.174s, BY onset: 0.176s, Holm onset: 0.178s

Onset/offset estimation methods were assessed using the median absolute error (MAE) and variance of 10.000 simulated datasets...

Application to actual MEG data

Assessing the reliability of the proposed approach using some sort of split-half reliability (e.g., Rosenblatt et al., 2018)? Using the MEG decoding results of Nalborczyk et al. (in preparation) in 33 participants:

- Create many (e.g., 10 or 20) half train/test splits of the data
- For each fold, estimate the onset/offset on both splits using all methods
- Then summarise the distribution of onset/offset with the median and variance across folds

This will allow checking that the proposed approach produces reliable onset/offset estimates.

Appendix A

Application to time-resolved decoding results (accuracy over time)

We conducted time-resolved multivariate pattern analysis (MVPA), also known as decoding.

As a result, we have a timecourse of decoding accuracies (e.g., ROC AUC), bounded between 0 and 1, per participant (Figure A1)...

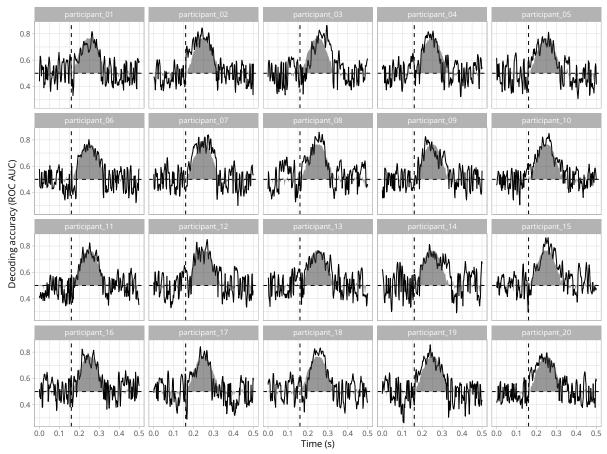

Figure A1

344

346

347

Exemplary average timecourse of binary decoding accuracy (ROC AUC) for each participant. Group-level average decoding accuracy is depicted as a grey background density in each panel.

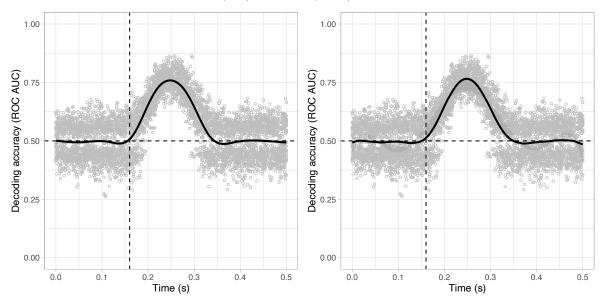

Now, we want to test whether the group-level average decoding accuracy is above chance (i.e., 0.5) at each timestep. We use a similar GAM/GP as previously, but we replace the Normal likelihood function by a Beta one to account for the bounded nature of AUC values (between 0 and 1).

```
# fitting the GAM
decoding_gam <- brm(
    auc ~ s(time, bs = "cr", k = 10),
    data = decoding_data,
    family = Beta(),
    iter = 5000,
    chains = 4,
    cores = 4,
    file = "models/decoding_gam.rds"
    )</pre>
```

```
# fitting the GP
decoding_gp <- brm(
    auc ~ gp(time, k = 20),
    data = decoding_data,
    family = Beta(),
    control = list(adapt_delta = 0.99),
    iter = 5000,
    chains = 4,
    cores = 4,
    file = "models/decoding_gp.rds"
    )</pre>
```

Figure A2

Posterior predictions of the GAM (left) and GP (right) fitted on decoding accuracy over time.

Next, we plot the posterior probability of decoding accuracy being above chance level (plus some epsilon) (Figure A3).

Figure A3

Posterior probability of decoding accuracy being above chance level according to the GAM (left) or the GP (right).

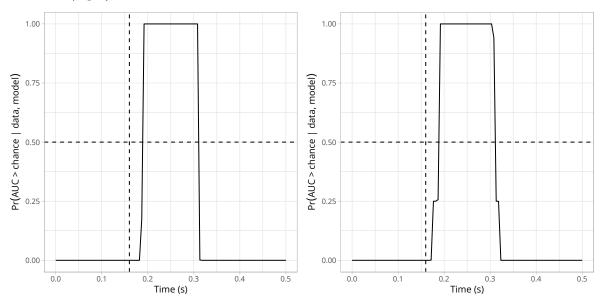

Figure A4

350

351

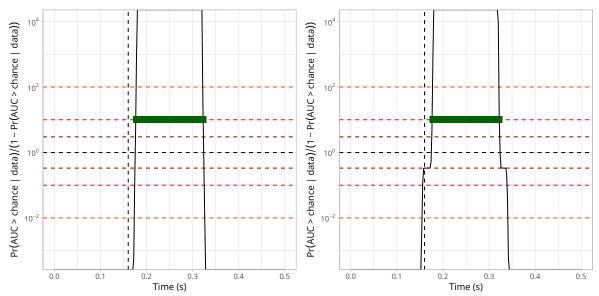

352

353

354

355

Ratio of posterior probabilities of decoding accuracy being above chance level according to the GAM (left) or the GP (right).

Appendix B

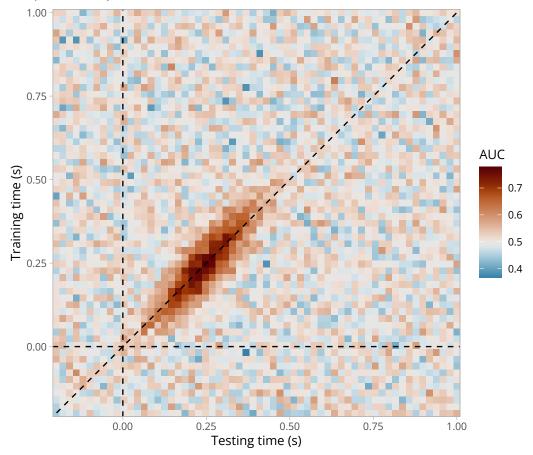

Application to 2D time-resolved decoding results (cross-temporal generalisation)

Assume we have M/EEG data and we have conducted cross-temporal generalisation analyses (King & Dehaene, 2014). As a result, we have a 2D matrix where each element contains the decoding accuracy (e.g., ROC AUC) of a classifier trained at timestep training_i and tested at timestep testing_i (Figure B1).

Now, we want to test whether and when decoding performance is above chance level (0.5 for a binary decoding task). These two models are computationally heavier to fit (more

Figure B1

Exemplary (simulated) group-level average cross-temporal generalisation matrix of decoding performance (ROC AUC).

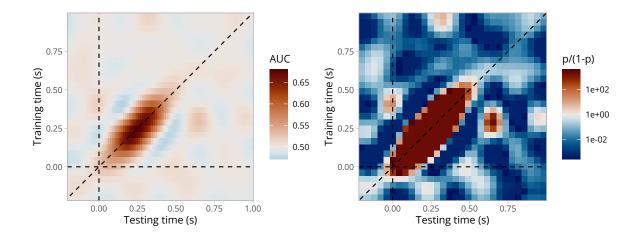

observations and 2D smooth functions)...

```
# fitting a GAM with two temporal dimensions
timegen_gam <- brm(</pre>
    # 2D thin-plate spline (tp)
    # auc ~ s(train_time, test_time, bs = "tp", k = 10),
    auc ~ t2(train_time, test_time, bs = "tp", k = 10),
    data = timegen_data,
    family = Beta(),
    iter = 5000,
    chains = 4,
    cores = 4,
    file = "models/timegen_gam_t2.rds"
\# fitting a GP with two temporal dimensions
# timegen_gp <- brm(</pre>
      auc ~ gp(train_time, test_time, k = 20),
      data = timegen_data,
#
      family = Beta(),
      control = list(adapt_delta = 0.95),

# file = "models/timegen_gp.rds"
# )
```

Figure B2

Posterior probability of decoding accuracy being above chance level (2D GAM).

Appendix C

Mathematical formulation of the bivariate GAM

To model cross-temporal generalisation matrices of decoding performance (ROC AUC), we extended the initial (decoding) GAM to take into account the bivariate temporal distribution of AUC values, thus producing naturally smoothed estimates (timecourses) of AUC values and posterior probabilities. This model can be written as follows:

$$AUC_i \sim Beta(\mu_i, \phi)$$

 $g(\mu_i) = f(train_i, test_i)$

where we assume that AUC values come from a Beta distribution with two parameters μ and ϕ . We can think of f (train_i, test_i) as a surface (a smooth function of two variables) that we can model using a 2-dimensional splines. Let $\mathbf{s}_i = (\text{train}_i, \text{test}_i)$ be some pair of training and testing samples, and let $\mathbf{k}_m = (\text{train}_m, \text{test}_m)$ denote the m^{th} knot in the domain of train_i and test_i. We can then express the smooth function as:

$$f(\text{train}_i, \text{test}_i) = \alpha + \sum_{m=1}^{M} \beta_m b_m \left(\tilde{s}_i, \tilde{k}_m\right)$$

Note that $b_m(,)$ is a basis function that maps $R \times R \to R$. A popular bivariate basis function uses thin-plate splines (Wood, 2003), which extend to $\mathbf{s}_i \in \mathbb{R}^d$ and ∂l_g penalties. These splines are designed to interpolate and approximate smooth surfaces over two dimensions (hence the "bivariate" term). For d=2 dimensions and l=2 (smoothness penalty involving second order derivative):

$$f(\tilde{s}_i) = \alpha + \beta_1 x_i + \beta_2 z_i + \sum_{m=1}^{M} \beta_{2+m} b_m \left(\tilde{s}_i, \tilde{k}_m\right)$$

using the the radial basis function given by:

$$b_m\left(\tilde{s}_i, \tilde{k}_m\right) = \left\|\tilde{s}_i - \tilde{k}_m\right\|^2 \log \left\|\tilde{s}_i - \tilde{k}_m\right\|$$

where $\|\mathbf{s}_i - \mathbf{k}_m\|$ is the Euclidean distance between the covariate \mathbf{s}_i and the knot location \mathbf{k}_m .

Appendix D

Threshold-free cluster enhancement

Cluster-based permutation approaches require defining a cluster-forming threshold (e.g., a tor f-value) as the initial step of the algorithm. As different cluster-forming thresholds lead to clusters with different spatial or temporal extent, this threshold modulates the sensitivity of the subsequent permutation test. The threshold-free cluster enhancement method (TFCE) was introduced by Smith & Nichols (2009) to overcome this arbitrary threshold.

In brief, the TFCE method works as follows. Instead of picking an arbitrary cluster-forming threshold (e.g., t=2), we try all (or many) possible thresholds in a given range and check whether a given timestep/voxel belongs to a significant cluster under any of the set of thresholds... Then, instead of using cluster mass, we use a weighted average between the cluster extend (e, how broad is the cluster, that is, how many connected samples it contains) and the cluster height (h, how high is the cluster, that is, how large is the test statistic) according to the formula:

$$TFCE = \int_{h} e(h)^{E} h^{H} dh$$

Where... the parameters E and H are set a priori and control the influence of the extend and height on the TFCE. Then, p-value for timestep/voxel i is computed by comparing it TFCE with the null distribution of TFCE values. For each permuted signal, we keep the maximal value over the whole signal for the null distribution of the TFCE.... But see Sassenhagen & Draschkow (2019)...

Appendix E Integration with MNE-Python

Explain how to use the R package with MNE epochs...
